Foreword

SEVERAL PACIFIC OCEAN BASIN tsunamis have been recognized as a potential hazard to United States coastal communities since the mid-twentieth century, when multiple destructive tsunamis caused damage to the states of Hawaii, Alaska, California, Oregon, and Washington. In response to these events, the United States, under the auspices of the National Oceanic and Atmospheric Administration (NOAA), established the Pacific and National Tsunami Warning Centers, dedicated to protecting United States interests from the threat posed by tsunamis. NOAA also created a tsunami research program at the Pacific Marine Environmental Laboratory (PMEL) to develop improved warning products.

The scale of destruction and unprecedented loss of life following the December 2004 Sumatra tsunami served as the catalyst to refocus efforts in the United States on reducing tsunami vulnerability of coastal communities, and on 20 December 2006, the United States Congress passed the “Tsunami Warning and Education Act” under which education and warning activities were thereafter specified and mandated. A “tsunami forecasting capability based on models and measurements, including tsunami inundation models and maps” is a central component for the protection of United States coastlines from the threat posed by tsunamis. The forecasting capability for each community described in the PMEL Tsunami Forecast Series is the result of collaboration between NOAA’s office of Oceanic and Atmospheric Research, National Weather Service, National Ocean Service, National Environmental Satellite, Data, and Information Service, the University of Washington’s Joint Institute for the Study of the Atmosphere and Ocean, the National Science Foundation, and the United States Geological Survey.

NOAA Center for Tsunami Research

PMEL Tsunami Forecast Series: Vol. 11

A Tsunami Forecast Model for Kihei, Hawaii

E. Gica^{1,2}

Abstract. The National Oceanic and Atmospheric Administration (NOAA) has developed a tsunami forecast model for Kihei, Hawaii, as part of an effort to provide tsunami forecasts for U.S. coastal communities. Development, validation, and stability testing of the tsunami forecast model has been conducted to ensure that it is stable and robust. The Kihei tsunami forecast model employs the Method of Splitting Tsunami (MOST) numerical code and has been validated with three historical tsunamis. A total of 13 historical events and 62 synthetic (Mw 9.4, 7.5, and 6.2) events from different source regions were also used to test the model’s stability and reliability. The Kihei forecast model remains stable for 24 hours, and has been developed to simulate 4 hours of tsunami wave characteristics in approximately 13.22 minutes of CPU time.

1. Background and Objectives

The National Oceanic and Atmospheric Administration (NOAA) Center for Tsunami Research (NCTR) at the Pacific Marine Environmental Laboratory (PMEL) has developed a tsunami forecasting capability for operational use by NOAA’s two Tsunami Warning Centers located in Hawaii and Alaska (Titov *et al.*, 2005). The system is designed to provide, in an efficient manner, a quick and accurate basin-wide warning of approaching tsunami waves. The system, termed Short-term Inundation Forecast of Tsunamis (SIFT), combines real-time tsunami event data with numerical models to produce estimates of tsunami wave arrival times and amplitudes at coastal communities of interest. The SIFT system integrates several key components: deep-ocean observations of tsunamis in real time, a basin-wide precomputed propagation database of water level and flow velocities based on potential seismic unit sources (Gica *et al.*, 2008), an inversion algorithm to refine the tsunami source based on deep-ocean observations during an event (Percival *et al.*, 2011), and high-resolution tsunami forecast models.

The town of Kihei is located on the southern coast (southwest of Haaleakalā) of Maui, Hawaii (**Figure 1**). Kihei has an average of 276 sunny days per year and temperatures ranging from 53°F (January) to 74°F (July). Historically, with less than 33 cm of rain each year, Hawaiians referred to it as “Kama’ole,” meaning barren. In 2010, Kihei was ranked as Hawaii’s tenth most populous census county division; the town’s population increased over the last decade from 16,749 to 20,881 (Census, 2000, 2010). With a census designation land area of 9.28 sq mi, this places its current population density over 2250 people per square mile. With lots of affordable condominiums, hotels, and cottages, Kihei has become a popular destination

1 Joint Institute for the Study of the Atmosphere and Ocean (JISAO), University of Washington, Seattle, WA

2 NOAA/Pacific Marine Environmental Laboratory (PMEL), Seattle, WA

for tourists (GoHawaii, 2014). Beyond tourism-based businesses, Kihei has built a presence in the technology sector, with the US Department of Defense's supercomputing resource center, The Maui High Performance Computing Center (MHPCC; <http://www.mhpcc.hpc.mil/>) and one of two Incubation Centers for High Technology Development Corporation (<http://www.htdc.org>).

This report details the development of a tsunami forecast model for Kihei, Hawaii. Development includes construction of a digital elevation model (DEM) based on available bathymetric and topographic data, model validation with historic events, and stability tests of the model with a suite of synthetic megatsunami events originating from subduction zones in the Pacific Ocean.

2. Forecast Methodology

A high-resolution inundation model, or “reference” model, is used as the basis for the development of a tsunami forecast model for Kihei, Hawaii. The main objective of a forecast model is to provide an operational estimate of wave arrival time, wave height, and inundation in the minutes immediately following a tsunami event, and to maximize the amount of time that the community at risk has to react to a tsunami threat by providing accurate information quickly to emergency managers and other officials responsible for the community and infrastructure. The Kihei tsunami forecast model was designed and tested to perform operationally under stringent time constraints, given that time is generally the single limiting factor in saving lives and property.

The tsunami forecast model, based on the Method of Splitting Tsunami (MOST; Titov and González, 1997; Titov and Synolakis, 1998), is used in the tsunami inundation and forecasting system to provide real-time tsunami forecasts for at-risk populous coastal communities in the Pacific and Atlantic oceans. MOST is a suite of numerical codes capable of simulating three processes of tsunami evolution: tsunami source generation, transoceanic propagation, and inundation of dry land. The MOST model has been extensively tested against a number of laboratory experiments and benchmarks (Synolakis *et al.*, 2008), and it has been successfully used for simulations of many historical tsunami events. Titov and González (1997) describe the technical aspects of forecast model development, stability, testing, and robustness, and Tang *et al.* (2009) provide detailed forecast methodology.

All tsunami forecast models are run in real time while a tsunami is propagating across the open ocean. The model runs in minutes while employing a high-resolution DEM constructed by the National Geophysical Data Center (NGDC) and NCTR³. From the DEM, three high-resolution “reference” elevation grids are constructed for the development of a high-resolution reference model, from which an “optimized” model is constructed to run in a specified period of time. This model is referred to as the optimized tsunami forecast model, or forecast model for brevity.

Accurate forecasting of tsunami impact on a coastal community largely relies on the accuracies of bathymetry, topography, and the numerical computation. The high spatial and temporal grid resolution necessary for modeling accuracy poses a challenge in the run-time requirement for real-time forecasts. Forecast models are optimized from the high-resolution grids using the most recent bathymetry and topography available to reproduce the correct wave dynamics during the inundation computation.

Previous and present development of forecast models in the Pacific (Titov *et al.*, 2005; Titov, 2009; Tang *et al.*, 2009; Wei *et al.*, 2008) have validated the accuracy and efficiency of each forecast model currently implemented in the real-time tsunami forecast system. Models are tested when the opportunity arises and are used for scientific research.

³ As new DEMs become available, forecast models will be updated and report updates will be posted at nctr.pmel.noaa.gov/forecast_reports/.

3. Model Development

The general methodology for modeling at-risk coastal communities is to develop a set of three nested grids (A, B, and C), each of which is successively finer in resolution, telescoping down with increasing spatial and temporal resolution to the population and economic center of the community of interest. The offshore area is covered by the largest and lowest-resolution A grid, while the nearshore details are resolved within the finest-scale C grid to capture the tsunami wave transformations in shallow waters.

The model development process begins with large spatial extent merged bathymetric-topographic grids at high resolution. Characteristics of tsunami waves are sensitive to nearshore bathymetry, and subaerial topography plays a factor in the inundation extent of tsunami waves. Therefore, a prerequisite for credible tsunami modeling is the availability of accurate gridded bathymetry and topographic datasets, or DEMs. The high-resolution DEM serving as the basis for these grids uses all available bathymetric, topographic, and shoreline data to reproduce the wave dynamics during the inundation computation for an at-risk community. The data are compiled from NOAA Coastal Services Center Interferometric Synthetic Aperture Radar (ifSAR), Navy SHOALS (Scanning Hydrographic Operation Airborne LIDAR Survey), National Ocean Service (NOS) digital echo sounder, and U.S. Geological Survey (USGS) multibeam seafloor mapping. The grids are then optimized by sub-sampling to coarsen the resolution and reduce the overall grid dimensions, to achieve a 4 to 10 hr simulation of modeled tsunami waves within 10 min of wall-clock time. All bathymetric data were converted from Mean Lower Low (MLL) datum to Mean High Water (MHW). The final DEM is referenced to MHW in the vertical and to the World Geodetic System 1984 (WGS84) in the horizontal (Chamberlin, 2007). The use of MHW as the “zero level” for forecast results is standard. The MOST model does not include tidal fluctuations, and, since a tsunami may arrive at any stage of the tide, it is best to employ a “worst-case” approach by assuming high tide when forecasting inundation.

Figure 1 shows the spatial extent merged bathymetric-topographic grids used in the development of the tsunami forecast model for Kihei, Hawaii. The author considers this to be an adequate representation of the local topography/bathymetry. **Table 1** provides specific details of both reference and forecast model grids, including extents, and complete input parameter information for the model runs is provided in Appendix A.

3.1 Forecast area

The town of Kihei, located on the southern coast of Maui, southwest of Haaleakalā, faces the Pacific Ocean and the neighboring islands of Lanai and Kahoolawe (**Figure 1**). South Kihei Road and Highway 31 (Piilani Highway) are the two main roads that run roughly parallel to the coastline. South Kihei Road runs along the coast and cuts through the town, while Highway 31 is farther east.

Table 1: MOST setup parameters of the reference and forecast models for Kihei, Hawaii.

Friction coefficient (n ²)			0.0009				0.0009		
CPU time for a 4 hr simulation			22.68 hr				13.22 min		

Computations were performed on a single Intel Xeon E5670 processor at 2.936 GHz, 12 M cache, Dell PowerEdge R510.

Figures 2c and **3c** show the contour of the coastal area where a large portion of land is at an elevation of 5 m or below and roughly 1–1.5 km from the coastline, providing a mild slope region where businesses and population are located. Generally, the elevation slowly increases another 5 m eastward and then quickly slopes toward the hills. A portion of the occupied area is located at the northeastern end of Highway 31 (**Figure 1**) at an approximate elevation of 40 m mean sea level (MSL). The MHPCC is located on the central east side of Highway 31 at a much higher elevation (50 m MSL).

A large portion of the coast features a small coastal shelf where the water depth slowly increases to 5 m depth, quickly drops another 5 m, and then encounters another mild slope. The bathymetry gets complicated farther offshore, with deeper depths clustered in concentrated areas. These areas are clearly seen on the southwest areas of **Figures 2c** and **3c**. Similar clusters are also found between 20.75°N and 20.76°N along 203.26°E. Another noteworthy feature is a “c” shape formed at the 10 m contour line along 20.76°N. The effects of this feature are seen in the maximum current speed distribution, discussed in Section 4.

3.2 Historical events and data

The Hawaiian Islands are located in the path of any tsunamis generated in the Pacific Ocean. With active subduction zones in the Pacific Basin, the potential for tsunamigenic earthquakes is high (Nishenko, 1991). The Hawaiian Islands have been hit by numerous tsunamis; some have caused millions of dollars in damage and loss of human lives (Alexandra *et al.*, 2009, NGDC/WDS, 2014). Historical records (**Table 2**) show tsunami runup in Kihei for the 1946 Unimak, 1957 Andeanof, and 1960 Chilean tsunamis, but there are no records of significant damage (NGDC, 2011). Although only these three historical tsunamis were recorded, simulations are conducted with other historical events to determine how the community of Kihei would be affected.

A basin-wide database of precomputed water elevations and flow velocities for unit sources covering worldwide subduction zones has been generated to expedite forecasts (Gica *et al.*, 2008). As the tsunami wave propagates across the ocean and successively reaches Deep-ocean Assessment and Reporting of Tsunamis (DART®) observation sites, recorded sea level is ingested into the tsunami forecast application in near-real time and incorporated into an inversion algorithm to produce an improved estimate of the tsunami source (Percival *et al.*, 2011). A linear combination of the precomputed database is then performed based on this improved tsunami source, now reflecting the transfer of energy to the fluid body, to produce boundary conditions of water elevation and flow velocities to initiate the forecast model computation. This process is reflected in **Table 3** under the heading *Model—Tsunami Source*.

Historical tide gauge records are not available for Kihei since no tide gauge was ever installed. The closest tide gauge is located on the other side of the island of Maui, in Kahului Harbor. Due to significant differences in wave characteristics at Kahului Harbor, the Kahului tide gauge cannot be used for model data comparison at Kihei; thus, a warning point was selected. The warning point for Kihei is located at 203.540277°E, 20.747685°N, at a depth of 1.74 m (**Figures 2c** and **3c**). The recent 2011 Tohoku tsunami caused minor flooding along the coast of Kihei, but historically, Kihei has not experienced significant tsunami damage. The islands of Lanai and Kahoolawe (**Figure 1**) may provide some protection from such damage by partially blocking Kihei from the open ocean. Depending on the location of the tsunami source, this island blocking effect might not hold true in all cases. This is tested by running synthetic mega-tsunami events from various sources in the Pacific region.

3.3 Model setup

Normally, the high-resolution DEM is developed by NGDC and NCTR using all available bathymetric, topographic, and shoreline data. For Kihei, the high-resolution DEM was developed at PMEL (Chamberlin, 2007) with a grid resolution of 1/3 arc sec and coverage extent of 156.55°W, 20.65°N to 156.2°W, 21.05°N (**Figure 4**). The A and B grids for Kihei are from those developed by Tang *et al.* (2010) to be consistent with the other inundation models developed in Hawaii. The C grid is extracted from the 1/3-arc-sec DEM discussed above.

The coverage extents of the C grid for the reference and forecast models are identical. **Table 1** shows the details of the nested grids (A, B, and C), including the modeling parameters used, and the plots of the forecast and reference models are shown in **Figures 2** and **3**, respectively.

Although the DEM used for the forecast and reference models is derived from the same source, the use of a different grid resolution to optimize the forecast model may produce instabilities in the grid. These are stabilized by making modifications to the DEM, either by correcting the specific point of instability manually or by smoothing a cluster of nodes if the single node causing the instability is not located. The difference between the DEMs used in the forecast and reference models is evident in **Figures 2c** and **3c**. A complicated bathymetry in the

Table 2: Historical events with recorded runup at Kihei, Hawaii.

Event	Earthquake Date Time [UTC]	Coverage [Lat, Lon]	Seismic Moment Magnitude [Mw]	Runup height at 20.785°N, 156.467°E [m]¹

deeper region is clearly visible in the higher-resolution reference model (lower left area along 203.26°E, **Figure 3c**), while it is much smoother in the forecast model (**Figure 2c**).

The forecast model is designed to provide 4 hr of simulated tsunami wave characteristics, including a time series at the selected warning point, within the operational time constraint of 10 min. For Kihei, the forecast model simulates 4 hr of tsunami wave characteristics in approximately 13.22 min, which exceeds this time constraint. The reason for this longer simulation is the use of a higher-resolution 1-arc-sec C grid for better representation of the DEM. The reference model, on the other hand, takes about 22.68 hr to complete the simulated run of 4 hr.

4. Results and Discussion

4.1 Model validation

In the development of the reference and forecast models for Kihei, Hawaii, validation of the DEM is required to determine the accuracy of the simulated tsunami characteristics as waves reach the coastal areas. As numerous tsunamis in the Pacific Basin have impacted the Hawaiian Islands, it seems likely that, historically, Kihei has been susceptible to tsunamis. Although the data are limited due to the absence of a tide gauge in Kihei, historical records for the three events listed in Section 3.2 (**Table 2**) will be used to validate the forecast model, and other historical events are simulated to determine how the waves affect the coastal areas of Kihei (**Table 3**). The locations of these historical events relative to Kihei are plotted in the upper panel of **Figure 5**.

4.2 Model stability and reliability

The forecast model must be stable enough to reliably simulate several hours of a tsunami event. A set of reliability and stability tests was conducted by simulating synthetic events emanating from different regions and using different earthquake magnitudes. Since each tsunami event is unique, tests using different earthquake magnitudes and source locations would indicate if the model grid developed will generate instabilities that need to be corrected. This set of tests is not exhaustive, but the inclusion of representative cases using unit sources from the NCTR propagation database (Gica *et al.*, 2008) should serve as a sufficient sample. A total of 41 synthetic mega-tsunami (Mw 9.4) events were generated from 20 unit sources with a slip value of 30 m for each unit source, and 20 cases of Mw 7.5 events were generated from one unit source with a slip of 1 m. One case of Mw 6.2 is also included to test the model for a small wave condition. Tests were conducted for a total of 24 hr simulation. **Tables 4** and **5** list the sources used for the synthetic mega-tsunami events and the smaller (Mw 7.5 and Mw 6.2) events, respectively. The location of the synthetic mega-tsunami events (**Table 4**) relative to Kihei are shown in the lower panel of **Figure 5**.

4.3 Results of tested events

The maximum tsunami wave amplitude distribution, inundation, tsunami time series, maximum tsunami current speed distribution, current speed, and directionality for the tested (historic and synthetic) events are presented in **Figures 6–21**. All the plots show results of both the forecast and reference models. The simulated tsunami time series, current speed, and directionality are recorded at the selected warning point (**Figures 2c** and **3c**). Comparison between the forecast and reference models for 13 historical events are shown in **Figures 6–18**, while **Figures 19–21** are representative plots for the synthetic mega-tsunami events. Plots of maximum tsunami amplitude distribution show if the coastal areas of

Kihei will be inundated. The maximum tsunami current speed distribution plots the maximum current speed, both at sea and on land as inundation occurs. The direction of the current is subdivided into four regions: west to north, south to west, east to south, and north to east. Relative to the coastline, this directionality indicates whether the incoming tsunami wave is advancing from the shore, retreating from the shore, or moving in an alongshore direction.

Due to the absence of a tide gauge in Kihei, tsunami time series comparisons are made only between the forecast and reference model, with the exception of a few historical events where records of tsunami runup are available (**Table 2**). In all of the historical cases, as seen in the tsunami time series at the warning point, the maximum tsunami wave amplitude for the reference model is higher than the forecast model (**Figures 6a–18a**), and the first tsunami wave matches very well between the reference and forecast model. The succeeding waves are much higher for the reference model but match well in phase. The lower maximum wave in the forecast model may be due to the grid resolution used. To increase the grid resolution, however, would result in a longer completion time, which (at 13.22 min) already exceeds the 10 min maximum completion time requirement.

Similar to the maximum tsunami wave amplitude results, the current speed at the warning point is much higher for the reference model. Finer wave patterns, visible in the reference model, are not present in the forecast model. Within the plot, it is worth noting that the southwest area of the C grid shows slightly different maximum current speed distribution for the reference model when compared to the forecast model (**Figures 6c–18c**). This is attributed to the complex bathymetry in that region, which is modified in the forecast model to generate a stable run (**Figures 2c and 3c**). Overall, both maximum tsunami wave amplitude distribution and maximum current speed distribution are similar between the forecast and reference models. Inundation extent was either nonexistent or insignificant for all of the 13 simulated historical cases.

Post-tsunami survey measurement runup data are available from NGDC for the three simulated historical cases (**Table 2**). For the 1946 Unimak tsunami, the record indicated a runup height of 2.7 m. The simulated result for this specific event produced a runup of approximately 1.78 m for the forecast model and 1.82 m for the reference model. For the 1957 Andreanof tsunami, the historical runup of 2.1 m exceeds the simulated results of 1.56 m for the forecast model and 1.68 m for the reference model. For both events, the distance from the simulated runup to the recorded runup is approximately 71 m for the forecast model and 63 m for the reference model. A runup of 2.4 m recorded for the 1960 Chile tsunami (NGDC, 2011) corresponds with a simulated 2.07 m runup by the forecast model and 2.36 m runup by the reference model, at distances of 71 m and 94 m away, respectively, from the recorded data.

Overall, the comparison of the simulated runup values with historical records for all three events (**Table 2**) show a higher runup for historical events. The simulated events were approximately 0.33 to 0.9 m below that of the historical record, and approximately 63 to 94 m away from the recorded runup location. The discrepancies may be due to the tsunami source used in the simulation, which still may not be well defined. Videos of the more recent 2011 Tohoku event have been posted online (e.g., YouTube, 2011) showing evidence of flooding in Kihei. Simulation of this event also indicates minor flooding along the coast (**Figure 18**). A tsunami survey in the state of Hawaii was conducted for the 2011 Tohoku event; field measurement data of inundation and runup can be used to validate the Kihei forecast model. However, during the development and testing of the Kihei model and at the time this report is being written, NCTR has not yet obtained these data. For the remaining historical events where historical data are not available, the forecast model is compared with the reference model.

The synthetic events simulated for the forecast model show that it is both stable and reliable. Although the mega-tsunami tests are not exhaustive, the results indicate which tsunami source regions would pose the greatest threat to Kihei. Of the 41 synthetic mega-tsunamis (**Table 4**), only 18 sources based on the forecast model (15 sources based on the reference model) produced very minor inundation along the coast of Kihei. **Table 6** lists the extent of inundation for each synthetic event simulated and **Figures 19–21** shows representative plots. **Figure 22** shows the locations of the low coastal impact synthetic mega-tsunami events relative to Kihei, clearly indicating that the main tsunami energy is directed away from Kihei. Tsunami sources that have extreme coastal impacts emanate from EPSZ 9–18,

KISZ 1–10, KISZ 11–20, KISZ 42–51, and MOSZ 1–10. A representative plot of extreme inundation based on EPSZ 9–18 is shown in **Figure 19**. The locations of these extreme tsunami sources relative to Kihei are shown in **Figure 23**. The inundation extent for these tsunami sources occupies a significant portion of the coastal town. The remaining 18 synthetic mega-tsunami events are not extreme but still produce significant tsunami impact.

Figure 24 plots the tsunami time series at the selected warning point for all synthetic mega-tsunami events for both forecast and reference models, again showing that, consistent with the simulation of historical events, the forecast model has a lower maximum wave than the reference model. As previously discussed, this may be attributable to the lower grid resolution used. Overall, the first couple of waves match well between the forecast and reference model.

In **Figures 6–21**, the plots showing the maximum tsunami wave amplitude distribution do not clearly demonstrate how the incoming tsunami waves interact with the coastal reef in Kihei. This interaction is clearly seen in the maximum tsunami current speed distribution plots. The current speed is high as the incoming tsunami waves encounter the 5 m offshore contour line of the coastal shelf. Its strength diminishes as it passes through the coastal shelf. However, depending on the location of the tsunami source relative to Kihei, the incoming waves could produce either no inundation or extreme inundation with high current speed as they reach the coastal areas. For synthetic mega-tsunami events (**Table 4**), the current speed on land is at least 5 m/sec, with an extreme case of around 10 m/sec for the EPSZ 9–18 source (**Figure 19**). The plot of the current directionality shows a complex pattern: the tsunami waves not only approach and recede from the shore, but also generate cross-currents.

5. Conclusions

Reference and forecast models have been developed for Kihei, Hawaii. Both models were found to be reliable, and demonstrated relatively good comparison to each other in all cases tested.

Three historical tsunami events produced documented runup in Kihei: 1946 Unimak, 1957 Andreanof, and 1960 Chile. For comparative purposes, these events were used to validate the reliability of the reference and forecast models. The simulated runup (for both forecast and reference models) was found, on average, to be 0.52 m less than the recorded runup and 72 m away from the observed location. This discrepancy could indicate that the source used by NCTR is still not well defined. For the 2011 Tohoku event, both reference and forecast models indicate minor flooding along the coast, but comparative data for this event were not available at the time this report was developed, and are therefore not included.

Further tests show that both the forecast and reference models are stable for a 24 hr simulation of both historical cases and synthetic sources with different earthquake magnitudes emanating from different source regions. A total of 62 (41 Mw 9.4, 20 Mw 7.5, and 1 Mw 6.2) events were simulated. In addition to testing the stability of the forecast model, the mega-tsunami (Mw 9.4) scenarios can be useful in hazard assessment by helping to identify the source regions that represent the greatest tsunami threat to Kihei and to assist the local community in evacuation planning. Based on the forecast model, the 41 mega-tsunami scenarios tested result in minor inundation along the coast from 18 sources, significant inundation from another 16 sources, close to extreme inundation from two sources, and extreme inundation from five sources.

In this report, the tsunami time series at the selected warning point and distribution of the maximum tsunami wave amplitude, as well as plots of the maximum current speed distribution and current directionality at the selected warning point are presented. The current direction at the selected warning point demonstrates the complex pattern of the tsunami waves. Synthetic mega-tsunami event testing shows that East Phillipines source region EPSZ 9–18 can produce a current speed on land of at least 5 m/sec.

This forecast model was developed to provide tsunami forecast capability for Kihei, so the DEM has been optimized to simulate 4 hr of tsunami wave characteristics in approximately 13.22 min. This run time exceeds the 10 min completion time requirement. The longer run time may be attributed to the finer grid resolution used in the forecast model to simulate tsunami waves that closely match the higher-resolution reference model. As presented in this report, the Kihei forecast model is expected to provide a reliable forecast during an event and remain stable for a 24 hr simulation.

Appendix A. Model input files for Kihei, Hawaii

Development of the tsunami forecast model for Kihei, Hawaii, occurred prior to parameter changes that were made to reflect modifications to the MOST model code. As a result, the input files for running the high-resolution reference inundation model and the optimized tsunami forecast model in MOST have been updated accordingly. The updated files for Kihei are provided below.

A1. Reference model *.in file for Kihei, Hawaii

```

0.0001      Minimum amplitude of input offshore wave (m)
1           Input minimum depth for offshore (m)
0.1         Input "dry land" depth for inundation (m)
0.0009      Input friction coefficient (n**2)
1           A and B grid runup flag (0=disallow, 1=allow)
300.0       Blow-up limit/max eta before blow-up (m)
0.3         Input time step (sec)
288000      Input number of steps
12          Compute "A" arrays every nth ime step, n=
2           Compute "B" arrays every nth ime step, n=
60          Input number of steps between snapshots
1           ...Starting from
1           ...Saving grid every nth node, n=

```

A2. Forecast model *.in file for Kihei, Hawaii

```

0.0001      Minimum amplitude of input offshore wave (m)
1           Input minimum depth for offshore (m)
0.1         Input "dry land" depth for inundation (m)
0.0009      Input friction coefficient (n**2)
1           A and B grid runup flag (0=disallow, 1=allow)
300.0       Blow-up limit/max eta before blow-up (m)
1           Input time step (sec)
288000      Input number of steps
10          Compute "A" arrays every nth ime step, n=
1           Compute "B" arrays every nth ime step, n=
30          Input number of steps between snapshots
1           ...Starting from
1           ...Saving grid every nth node, n=

```

Appendix B. Propagation Database

Pacific Ocean Unit Sources

The NOAA propagation database presented in this section is the representation of the database as of January 2013, and may not be the most current version of the database available upon publication. The forecast model for Kihei, Hawaii, was developed using the propagation database as of 2011; thus, there is a possibility of changes due to updates in the earthquake source parameters.

Figure B1: Aleutian–Alaska–Cascadia Subduction Zone unit sources.

Table B1: Earthquake parameters for Aleutian–Alaska–Cascadia Subduction Zone unit sources.

Segment	Description	Longitude (°E)	Latitude (°N)	Strike (°)	Dip (°)	Depth (km)

Appendix C.

Synthetic Testing: Kihei, Hawaii*

C1. Purpose

An effective forecast model must provide reliable and stable data for several hours of simulation. This is accomplished by testing the model with a set of synthetic tsunami events covering a range of tsunami source locations and magnitudes. Testing is also done with selected historical tsunami events when available.

The purpose of forecast model testing is three-fold. The first objective is to assure that the results obtained with NOAA's tsunami forecast system, which has been released to the Tsunami Warning Centers for operational use, are consistent with those obtained by the researcher during the development of the forecast model. The second objective is to test the forecast model for consistency, accuracy, time efficiency, and quality of results over a range of possible tsunami locations and magnitudes. The third objective is to identify bugs and issues in need of resolution by the researcher who developed the forecast model or by the forecast software development team before the next version release to NOAA's two Tsunami Warning Centers.

Local hardware and software applications are used with tools familiar to the researcher(s) to run the Method of Splitting Tsunami (MOST) model during the forecast model development. The test results presented in this report lend confidence that the model performs as developed and produces the same results when initiated within the forecast application in an operational setting as those produced by the researcher during the forecast model development. The test results assure those who rely on the tsunami forecast model for Kihei, Hawaii, that consistent results are produced irrespective of system.

C2. Testing procedure

The general procedure for forecast model testing is to run a set of synthetic tsunami scenarios and a selected set of historical tsunami events through the forecast system application, and to compare the results with those obtained by the researcher during the forecast model development (as presented in the Tsunami Forecast Model Series report). Specific steps taken to test the model include:

1. Identification of testing scenarios, including the standard set of synthetic events, appropriate historical events, and customized synthetic scenarios that may have been used by the researcher(s) in the development of the forecast model.
2. Creation of new events to represent customized synthetic scenarios used by the researcher(s) in the development of the forecast model, if any.

* Authors: Edison Gica, Lindsey Wright

3. Submission of test model runs with the forecast system, and export of the results from A, B, and C grids, along with time series.
4. Recording applicable metadata, including the specific version of the forecast system used for testing.
5. Examination of forecast system model results for instabilities in both time series and plot results.
6. Comparison of forecast model results obtained through the forecast system with those obtained during the forecast model development.
7. Summarization of results with specific mention of quality, consistency, and time efficiency.
8. Reporting of issues identified to modeler and forecast software development team.
9. Retesting the forecast models in the forecast system when reported issues have been addressed or explained.

Synthetic model runs were tested on a DELL PowerEdge R510 computer equipped with two Xeon E5670 processors at 2.93 GHz, each with 12 MBytes of cache and 32 GB memory. The processors are hex core and support hyperthreading, resulting in the computer performing as a 24 processor core machine. Additionally, the testing computer supports 10 Gigabit Ethernet for fast network connections. This computer configuration is similar or the same as the configurations of the computers installed at the Tsunami Warning Centers so the compute times should only vary slightly.

C3. Results

The Kihei forecast model was tested using NOAA's tsunami forecast system version 3 with MOST version 2. Four synthetic scenarios and one historical tsunami event were included in this testing. Test results from the forecast system and comparisons with the results obtained during forecast model development are shown numerically in **Table C1** and graphically in **Figures C1–C5**.

The results show that the forecast model is stable and robust, with consistent and high-quality results across geographically distributed tsunami sources and mega-tsunami event magnitudes. The model run time (wall-clock time) was under 21.5 min for 8 hr of simulation time, and under 10.7 min for 4 hr, close to satisfying the time efficiency criterion of 10 min run time for 4 hr of simulation time.

For direct comparison purposes, a slip of 30 m is used rather than the standard 25 m for the four synthetic events run on the Kihei forecast model. The modeled scenarios are stable for all cases tested, with no instabilities or ringing. Amplitudes greater than 100 cm were recorded for all test sources. The largest modeled amplitude, at 533 cm, originated within the Kamchatka-Yap-Mariana-Izu-Bonin source KISZ 22–31. The smallest signal of 184 cm was recorded at the Aleutian-Alaska-Cascadia source ACSZ 56–65. The largest modeled tsunami wave amplitude noted here is based only on four synthetic events (**Table C1**) and does not represent the largest tsunami wave amplitude from the 62 events tested during development.

The maximum and minimum tsunami amplitudes obtained during the forecast model development differ from those tested with the tsunami forecast system. This is primarily attributed to the output time step increment. During development, an output time step of 60 sec was used, while the tsunami forecast system uses a time step of 30 sec. Additionally, there are possible changes in the propagation unit sources used since the Kihei model was developed in 2011. Overall, direct comparisons of output from the forecast model with results of both the 2011 Tohoku event and available synthetic events demonstrate that the wave patterns at the selected warning point are nearly identical.

Table C1: Maximum and minimum amplitudes (cm) at the Kihai, Hawaii, warning point for synthetic and historical events tested using SIFT 3.2 and obtained during development.

Scenarios	Source Zone	Tsunami Source	α [m]	Max (cm)		Min (cm)	
				SIFT	Development	SIFT	Development

Sea surface elevation time series at the C-grid warning point (d). The lower time series plot displays the result obtained during model development, shown for comparison with test results.

Glossary

Arrival time The time when the first tsunami wave is observed at a particular location, typically given in local and/or universal time, but also commonly noted in minutes or hours relative to the time of the earthquake.

Bathymetry The measurement of water depth of an undisturbed body of water.

Cascadia Subduction Zone Fault that extends from Cape Mendocino in Northern California northward to mid-Vancouver Island, Canada. The fault marks the convergence boundary where the Juan de Fuca tectonic plate is being subducted under the margin of the North America plate.

Current speed The scalar rate of water motion measured as distance/time.

Current velocity Movement of water expressed as a vector quantity. Velocity is the distance of movement per time coupled with direction of motion.

Deep-ocean Assessment and Reporting of Tsunamis (DART[®]) Tsunami detection and transmission system that measures the pressure of an overlying column of water and detects the passage of a tsunami.

Digital Elevation Model (DEM) A digital representation of bathymetry or topography based on regional survey data or satellite imagery. Data are arrays of regularly spaced elevations referenced to a map projection of the geographic coordinate system.

Epicenter The point on the surface of the earth that is directly above the focus of an earthquake.

Far-field Region outside of the source of a tsunami where no direct observations of the tsunami-generating event are evident, except for the tsunami waves themselves.

Focus The point beneath the surface of the earth where a rupture or energy release occurs due to a buildup of stress or the movement of Earth's tectonic plates relative to one another.

Inundation The horizontal inland extent of land that a tsunami penetrates, generally measured perpendicularly to a shoreline.

Marigram Tide gauge recording of wave level as a function of time at a particular location. The instrument used for recording is termed a marigraph.

Method of Splitting Tsunami (MOST) A suite of numerical simulation codes used to provide estimates of the three processes of tsunami evolution: tsunami generation, propagation, and inundation.

Moment magnitude (M_w) The magnitude of an earthquake on a logarithmic scale in terms of the energy released. Moment magnitude is based on the size and characteristics of a fault rupture as determined from long-period seismic waves.

Near-field Region of primary tsunami impact near the source of a tsunami. The near-field is defined as the region where non-tsunami effects of the tsunami-generating event have been observed, such as earth shaking from the earthquake, visible or measured ground deformation, or other direct (non-tsunami) evidences of the source of the tsunami wave.

Propagation database A basin-wide database of precomputed water elevations and flow velocities at uniformly spaced grid points throughout the world oceans. Values are computed from tsunamis generated by earthquakes with a fault rupture at any one of discrete 100×50 km unit sources along worldwide subduction zones.

Runup Vertical difference between the elevation of tsunami inundation and the sea level at the time of a tsunami. Runup is the elevation of the highest point of land inundated by a tsunami as measured relative to a stated datum, such as mean sea level.

Short-term Inundation Forecasting for Tsunamis (SIFT) A tsunami forecast system that integrates tsunami observations in deep ocean with numerical models to provide an estimate of tsunami wave arrival and amplitude at specific coastal locations while a tsunami propagates across an ocean basin.

Subduction zone A submarine region of the earth's crust at which two or more tectonic plates converge to cause one plate to sink under another, overriding plate. Subduction zones are regions of high seismic activity.

Synthetic event Hypothetical events based on computer simulations or theory of possible or even likely future scenarios.

Tele-tsunami or distant tsunami or far-field tsunami Most commonly, a tsunami originating from a source greater than 1000 km away from a particular location. In some contexts, a tele-tsunami is one that propagates through deep ocean before reaching a particular location without regard to distance separation.

Tidal wave Term frequently used incorrectly as a synonym for tsunami. A tsunami is unrelated to the predictable periodic rise and fall of sea level due to the gravitational attractions of the moon and sun; see **Tide**, below.

Tide The predictable rise and fall of a body of water (ocean, sea, bay, etc.) due to the gravitational attractions of the moon and sun.

Tide gauge An instrument for measuring the rise and fall of a column of water over time at a particular location.

Travel time The time it takes for a tsunami to travel from the generating source to a particular location.

Tsunami meter An oceanographic instrument used to detect and measure tsunamis in the deep ocean. Tsunami measurements are typically transmitted acoustically to a surface buoy that in turn relays them in real time to ground stations via satellite.

Tsunami A Japanese term that literally translates to “harbor wave.” Tsunamis are a series of long-period shallow water waves that are generated by the sudden displacement of water due to subsea disturbances such as earthquakes, submarine landslides, or volcanic eruptions. Less commonly, meteoric impact to the ocean or meteorological forcing can generate a tsunami.

Tsunami hazard assessment A systematic investigation of seismically active regions of the world oceans to determine their potential tsunami impact at a particular location. Numerical models are typically used to characterize tsunami generation, propagation, and inundation, and to quantify the risk posed to a particular community from tsunamis generated in each source region investigated.

Tsunami propagation The directional movement of a tsunami wave outward from the source of generation. The speed at which a tsunami propagates depends on the depth of the water column in which the wave is traveling. Tsunamis travel at a speed of 700 km/hr (450 mi/hr) over the average depth of 4000 m in the open deep Pacific Ocean.

Tsunami source Location of tsunami origin, most typically an underwater earthquake epicenter. Tsunamis are also generated by submarine landslides, underwater volcanic eruptions, or, less commonly, by meteoric impact of the ocean.

Wall-clock time The time that passes on a common clock or watch between the start and end of a model run, as distinguished from the time needed by a CPU or computer processor to complete the run, typically less than wall-clock time.

Wave amplitude The maximum vertical rise or drop of a column of water as measured from wave crest (peak) or trough to a defined mean water level state.

Wave crest or peak The highest part of a wave or maximum rise above a defined mean water level state, such as mean lower low water.

Wave height The vertical difference between the highest part of a specific wave (crest) and its corresponding lowest point (trough).

Wavelength The horizontal distance between two successive wave crests or troughs.

Wave period The length of time between the passage of two successive wave crests or troughs as measured at a fixed location.

Wave trough The lowest part of a wave or the maximum drop below a defined mean water level state, such as mean lower low water.
